

How Do Individuals Repay Their Debt? The Balance-Matching Heuristic[†]

By JOHN GATHERGOOD, NEALE MAHONEY, NEIL STEWART, AND JÖRG WEBER*

We study how individuals repay their debt using linked data on multiple credit cards. Repayments are not allocated to the higher interest rate card, which would minimize the cost of borrowing. Moreover, the degree of misallocation is invariant to the economic stakes, which is inconsistent with optimization frictions. Instead, we show that repayments are consistent with a balance-matching heuristic under which the share of repayments on each card is matched to the share of balances on each card. Balance matching captures more than half of the predictable variation in repayments and is highly persistent within individuals over time. (JEL D14, D15, D91, G41)

Borrowing decisions underpin a broad set of economic behavior. Individuals borrow to smooth their consumption over the life cycle, invest in human capital, and purchase durable goods, among other reasons. Thus, understanding how individuals borrow is an important input for many fields of economic research and is directly relevant for consumer financial policy.

In this paper, we examine competing models of how individuals make debt payments, and thus implicitly how to borrow, across their portfolio of credit cards. We have a dataset with rich information on credit card contract terms, monthly statements, and repayments for 1.4 million individuals in the United Kingdom over a two-year period. Unlike other leading credit card datasets, our data allow us to link together multiple credit card accounts held by the same individual.¹ We study how

¹ For instance, neither the OCC's Consumer Credit Panel nor the CFPB's Credit Card Database are designed to permit linking of accounts held by the same individual. The credit bureau datasets that combine information from

individuals choose to allocate repayments across their credit cards, holding the total repayment in each month fixed.²

The credit card repayment decision is an ideal laboratory for studying borrowing because behavior that minimizes interest charges, what we refer to as optimal behavior, can be clearly defined. Consider individuals with debt on exactly two cards: holding the total amount repaid fixed, it is optimal for these individuals to make the minimum payment on both cards, repay as much as possible on the high interest rate card, and only allocate further payments to the low interest rate card if they are able to pay off the high interest rate card in full. What sets the credit card repayment decision apart from many other financial decisions is that optimal behavior does not depend on preferences, such as risk preferences or time preferences.³ This allows us to evaluate models of behavior without having to jointly estimate preference parameters.

The first part of the paper documents that individuals do not optimally allocate their payments across cards. Our baseline analysis focuses on individuals who hold exactly two cards in our dataset. For these individuals, the average difference in Annual Percentage Rate (APR) between the high and low interest rate cards is 6.3 percentage points, approximately one-third of the average 19.7 percent APR in our sample. If these individuals were completely unresponsive to interest rates, it is natural to assume that they would allocate 50.0 percent of their payments to each card on average. To minimize interest charges, we calculate that individuals should allocate 97.1 percent of the payments in excess of the minimum to the high APR card.⁴ We show that individuals allocate only 51.5 percent of their excess payments to the high APR card, behavior that is virtually indistinguishable from the completely non-responsive baseline. In other words, 85 percent of individuals should put 100 percent of their excess payments on the high interest rate card but only 10 percent do so.⁵

This finding of non-optimal repayments closely matches prior research by Ponce, Seira, and Zamarripa (2017) on credit card borrowing in Mexico. In particular, the most comparable result is that the share of payments in excess of the minimum misallocated to the high APR card is 50 percent among Mexican credit card holders and 46 percent among UK credit card holders. A possible explanation for the non-optimal repayments was that Mexican borrowers may not have had enough

multiple accounts held by the same individual do not have information on interest rates or repayments. There are a number of opt-in panels such as the Mint.com data and Lightspeed Research's Ultimate Consumer Panel that have information on multiple cards, but only for a self-selected sample of individuals.

²This type of allocative decision is common. In the UK market that we study, 46.1 percent of credit card holders have 2 or more cards, and this group accounts for 72.2 percent of outstanding balances (Financial Conduct Authority 2016). In the US market, 71.5 percent of credit card holders have 2 or more cards, and this group accounts for 91.8 percent of balances (authors' calculations using a representative sample of 2015 TransUnion credit bureau data).

³For example, optimal mortgage choices depend on risk preferences (in the decision to use an adjustable or fixed rate mortgage) and time preferences over the real option to refinance in the future (see Campbell and Cocco 2003). There are very few institutional settings in which optimal mortgage choices can be clearly defined, such as in the Danish mortgage market (see Andersen et al. 2017). The optimal credit card *spending* allocation depends on rewards programs, such as cash-back or airline points. Even when the terms of the rewards program are known, the optimal spending allocation depends on individuals' (idiosyncratic) value of features.

⁴The number is not exactly 100 percent because sometimes individuals can pay off the full balance by allocating a smaller amount, in which case they should allocate the remaining amount to the low interest rate card.

⁵In Section II, we show that this result extends to the samples where we observe individuals allocating repayments across three, four, and five cards.

experience with credit cards, or enough financial sophistication, compared to borrowers in highly-developed countries. The results in our paper show, to the contrary, the same degree of non-optimal repayments even in the United Kingdom, providing a striking example of uniformity of a behavioral bias across very different cultures and financial settings.⁶

The second part of the paper examines whether optimization frictions can explain the observed repayment behavior. In optimal inattention models, individuals face a fixed cost of optimization, such as the time, psychological, or cognitive costs associated with determining the optimal repayment allocation (Sims 2003). Because of this fixed cost, these models predict that the degree of misallocation should be decreasing in the financial stakes of the repayment decision. We show, however, that the share of misallocated repayments is invariant to the difference in interest rates across cards (which can be as large as 15 percentage points), the size of the repayment amount (which can be as high as £800 in a month), as well as a combined measure of the “financial stakes” of the repayment decision. We also show that the degree of misallocation is invariant to the time since account opening, suggesting that a learning model cannot explain observed behavior.⁷

The third part of the paper considers a number of different heuristics that might better explain repayment behavior. We consider a balance-matching heuristic under which the share of repayments on each card is matched to the share of balances on each card. Balance matching could arise from the salient placement of balances on credit card statements and the broad tendency for humans, and other species, to engage in “matching behavior” in related choice environments. Balance matching could also arise from individuals repaying a constant percentage of the balance on each card in a given month, a rule-of-thumb that would lead to inefficient behavior on both the allocative and extensive margins. We also consider five alternative heuristics, including a $1/N$ heuristic (Benartzi and Thaler 2001), in which payments are split evenly across cards, and the “debt snowball method,” in which payments are concentrated on the card with the lowest balance, as recommended by some financial advisors.⁸

We assess the explanatory power of these different repayment models using standard measures of goodness-of-fit (root mean square error, mean absolute error, Pearson’s ρ). To provide a lower benchmark, we calculate goodness-of-fit under the assumption that the percentage of repayments on the high APR card is randomly drawn from a uniform distribution with support on the 0 percent to 100 percent interval. To provide an upper benchmark, we use machine learning techniques to find the repayment model that maximizes out-of-sample fit using a rich set of explanatory variables.

⁶The United Kingdom has a long history and high rate of credit card use. Credit cards were introduced in the United Kingdom in 1966, making it the second country after the United States to adopt credit cards. The share of adults with a credit card is 60 percent in the United Kingdom (UK Cards Association 2017) relative to 9.5 percent in Mexico (BBVA 2015).

⁷Misallocation is similarly invariant to the number of days between payment dates, suggesting that frictions in coordinating repayments across cards with different due dates cannot explain repayment behavior.

⁸For example, see syndicated radio host Dave Ramsey: <https://www.daveramsey.com/blog/get-out-of-debt-with-the-debt-snowball-plan>. Also see Amar et al. (2011) and Brown and Lahey (2015) for experimental studies that investigate this hypothesis.

We find that balance matching captures more than half of the “predictable variation” in repayment behavior. That is, based on the range determined by the lower benchmark of random repayments and the upper benchmark of the machine learning models, we find that balance matching is closer to the upper benchmark on all of our measures. We also show that the optimal repayment rule and the other heuristic models do not come close to balance matching in their ability to match the data, capturing less than one-quarter of the predictable variation for most measures.⁹ In sensitivity analysis, we show that our results are robust to two potential threats to validity. First, we show that our results are not explained by anchoring on minimum payments (Stewart 2009, Navarro-Martinez et al. 2011, Keys and Wang forthcoming). Second, we show that our results are not driven by individuals using automatic payments (autopay), which is rarely used in our baseline sample.

We also evaluate each of our models in “horse race” type analysis where we determine the best fit model on an individual \times month basis. In binary tests, balance matching has the best fit for twice as many observations as either the random, optimal, or other heuristics models. In specifications where we allow for multiple types, balance matching is the best fit model for roughly half of the observations in our sample. We also show that balance matching exhibits a high degree of persistence within individuals over time, suggesting that balance matching is more than a good statistical model but is actually capturing a stable feature of individual decision-making.

In addition to providing us with an upper benchmark, the machine learning models allow us to assess the relative importance of interest rates versus balances in predicting repayment behavior. Consistent with the poor fit of the optimal repayment rule, we find that interest rates have low variable importance (i.e., proportional increase in R^2) in our machine learning models. Consistent with the balance matching results, we find that balances have the highest variable importance, with variable importance substantially larger than any of the other explanatory variables. Unlike some other machine learning applications (e.g., Mullainathan and Spiess 2017), these results are robust across partitions of the data.

Our findings are related to a number of strands of research. The finding of non-optimal repayments is closely related to the aforementioned Ponce, Seira, and Zamarripa (2017) study on credit card borrowing in Mexico, and more broadly related to a larger literature on non-optimal behavior in consumer financial markets (e.g., Agarwal, Skiba, and Tobacman 2009; Keys, Pope, and Pope 2016; Jørring 2018).¹⁰

Our investigation of optimal inattention models contributes to active literature on the explanatory power of these frameworks. For instance, consistent with our findings, Chetty et al. (2014) show that individuals in Denmark are inattentive in their pension contributions regardless of the economic stakes, pushing against models of optimal inattention. In contrast, in online experiments, Taubinsky and Rees-Jones (2018) find sharp evidence that attention to taxes is increasing in tax rates, supporting

⁹The one exception is the $1/N$ heuristic, which captures some behavior exactly, and has a comparable goodness-of-fit with the root mean square error metric.

¹⁰Our paper is more broadly related to a literature that examines how credit card utilization responds to changes in contract terms and shocks to income (e.g., Gross and Souleles 2002, Agarwal et al. 2018, Olafsson and Pagel 2018).

these models. While we do not believe there is a single correct model for behavior, our results suggest that in the credit card repayment domain, optimal inattention models have little explanatory power.

The balance matching result relates to a well-established literature in psychology on matching behavior. In a seminal paper, Herrnstein (1961) showed that pigeons peck keys for food in proportion to the time it takes for the keys to rearm rather than concentrating their effort on the key that rearms most quickly. This behavior, which became known as the “matching law,” has since been documented across a number of species. More recently, a large experimental literature has shown evidence of “probability matching” in repeated choice experiments. For instance, when faced with repeated choices between a gamble with a 70 percent chance of winning and one with a 30 percent chance of winning, subjects choose gambles in proportion to the chances of winning, even though choosing the gamble with the higher payoff is a dominant strategy (see Vulkan 2000 for a review). We discuss this literature, and our relation to it, in more depth in Section IV. To the best of our knowledge, our paper provides the first evidence of matching in the field.¹¹

The caveats to our analysis largely stem from the fact that we focus on the allocative decision of how individuals split repayments across their portfolio of credit cards. While this decision greatly simplifies the analysis, our estimates of the degree of non-optimal behavior should be interpreted as lower bounds relative to a counterfactual in which individuals could additionally reallocate payments across non-credit card loans (such as mortgages or automobile loans) or make adjustments on the extensive margin (e.g., by adjusting the trade-off between debt repayment and consumption). As we mention above, our focus on the allocative decision also naturally leads us to consider “allocative heuristics,” such as balance matching, rather than heuristics that determine behavior on the extensive margin (repaying a fixed percentage of the balances).

The rest of the paper proceeds as follows. Section I describes our data and presents summary statistics for our baseline sample. Section II presents our results on the optimality of repayment behavior. Section III tests whether optimal inattention and learning can fit the observed behavior. Section IV lays out alternative heuristics for debt repayment, including the balance-matching heuristic. Section V tests between these repayment models. Section VI discusses the implications of these results for the industrial organization of credit card markets and public policy. Section VII concludes.

I. Data

A. Argus Credit Card Data

Our data source is the Argus Information and Advisory Services’ Credit Card Payments Study (CCPS). The CCPS has detailed information on contract terms and billing records from five major credit card issuers in the United Kingdom. These issuers have a combined market share of over 40 percent and represent a broad

¹¹ See DellaVigna (2009) for a review of the evidence on choice heuristics using field data.

range of credit card products and market segments. We have obtained monthly data covering January 2013 to December 2014 for a 10 percent representative sample of individuals in the CCPS who held a credit card with at least 1 of the 5 issuers. Unlike other leading credit card datasets, the CCPS provides us with anonymized individual-level identifiers that allow us to link together multiple accounts held by the same individual (see footnote 1).¹²

B. Sample Restrictions

Our interest lies in understanding how individuals make repayment decisions across their portfolio of credit cards. Holding multiple cards is not uncommon. In the UK market, 46.1 percent of credit card holders have 2 or more cards, and individuals with 2 or more cards account for 72.2 percent of outstanding balances (Financial Conduct Authority 2016).¹³

Our unit of analysis is the individual \times month. In the remainder of the paper, we refer to individual \times months interchangeably as “observations.” All of the credit cards in our data require payments at a monthly frequency. We consider cards to be in the same “month” if their billing cycles conclude in the same calendar month. Since billing cycles often conclude near the end of the calendar month, payment dates are often quite near to each other.¹⁴ We construct separate samples based on the number of credit cards held by the individual in that month in our dataset (e.g., two cards, three cards, and so on). This is a weak lower bound on the number of cards held by the individual. In the analysis that follows, we typically start by presenting our methodology and results for the two-card sample, and then examine how our findings extend to individuals with three or more cards.

We implement our sample restrictions at the individual \times month level, excluding months that do not satisfy our restrictions, but otherwise keeping these individuals in our sample. To focus on repayment decisions, we drop observations where individuals are delinquent or have defaulted on at least one card in their portfolio, or where individuals pay less than the minimum due or more than the full balance on at least one card.¹⁵ Together, these restrictions drop 2.0 percent of individuals and 4.2 percent of aggregate revolving debt from the two-card sample. Second, we focus on observations in which individuals hold debt on all of their cards, i.e., they are carrying “revolving” balances. This ensures that allocating repayments toward the high

¹²While we do not have data that would allow us to comprehensively examine the representativeness of the CCPS data, the distribution of interest rates in the CCPS is very similar to the aggregate distribution reported in UK Cards Association (2013), suggesting that the CCPS is roughly representative of the entire market.

¹³These numbers are even higher in the US market. Using a representative sample of 2015 TransUnion data, we calculate that 71.5 percent of credit card holders have 2 or more cards, and individuals with 2 or more cards account for 91.8 percent of balances and 91.7 percent of revolving balances.

¹⁴In the two-card sample, two-thirds of observations have payment dates that are ten days apart or fewer. See online Appendix Figure A4 for a histogram of the difference in due dates between cards.

¹⁵Paying less than the minimum or more than full balance sometimes results from “mistakes” that are difficult to interpret with an allocative model of behavior. For instance, zero payments sometimes result from “forgetting” to put a check in the mail. Similarly, overpayments sometimes result from refunds that are processed after the individual decides on their payment, which reduce the balance below the payment amount.

APR card, in the manner described in Section II, minimizes interest charges.^{16,17} These restrictions remove a further 25 percent of individuals from the two-card sample. However, since most of these individuals do not have revolving debt (i.e., they are “transactors” who repay the balances in full each month), we only drop 12.7 percent of aggregate revolving debt.

Third, we make a number of sample restrictions so that we focus on observations where individuals, holding fixed total monthly repayments, have scope to reallocate payments across cards and therefore face an *economically meaningful* allocative decision. In particular, we drop a small number of observations where the interest rate is identical across cards, since any reallocation of payments has no impact on the cost of borrowing. We then drop observations where the individual pays either the full balance or the minimum payment on all of their cards, since these individuals do not have any payments to reallocate. Taken together, this third set of restrictions drops an additional 35.4 percent of individuals and 24.9 percent of aggregate revolving debt in the two-card sample. Online Appendix Table A1 goes through the third set of restrictions one-by-one. Most of the reduction is due to dropping individuals who pay exactly the minimum on each card.

Table 1 presents summary statistics on the baseline two-card sample. The average difference in APR (for purchases) between the high and low interest rate cards is 6.3 percentage points, or approximately one-third of the 19.7 percent average purchase APR in the sample.¹⁸ Yet despite this substantial difference in prices, utilization is remarkably similar. Purchases are £128 on the high APR card versus £117 on the low APR card; repayments are £260 on the high APR card versus £230 on the low APR card; and revolving balances are £2,200 on the high APR card versus £2,054 on the low APR card. This is particularly striking given that credit limits are almost three times larger than revolving balances on average, indicating that the typical individual would be able to shift all of their borrowing to the low APR card without exceeding their credit limit.

II. Optimal Repayments

In this section, we compare actual and interest-cost-minimizing allocation of repayments across cards. We refer to the interest-cost-minimizing allocation as the “optimal” allocation because it is hard to think of a (reasonable) scenario where minimizing interest costs would not be optimal. Holding the total repayment amount

¹⁶A (complicated) feature of credit cards is that if an individual carries no revolving balance at the beginning of the month, and repays the balance in full, they avoid any interest charges that month. If an individual carries a revolving balance at the beginning of the month, interest charges are incurred on average daily balance irrespective of whether the card is repaid in full. We focus on individuals who begin the month with revolving balances on all cards as it is unambiguously interest-cost-minimizing for these individuals to allocate repayments toward the high APR card. In other scenarios, it could be interest-cost-minimizing to allocate repayments toward the low APR (although our back-of-the-envelope calculations suggest this is unlikely).

¹⁷One consequence of this restriction is that we omit individuals who have two cards but hold revolving balances on only one card. In doing so, one potential concern is that we drop individuals who have “fully optimized” by completely paying off their high interest rate card. If this were the case, then our sample would be selected on individuals who failed to optimize, raising issues of external validity. However, among individuals who carry debt on only one card, the majority (61.8 percent) carry debt on only the high interest rate card, indicating that our sample is not selected in this manner.

¹⁸This difference does reflect short-term 0 percent promotional interest rate offers, which account for less than 5 percent of account \times month observations in the baseline sample.

TABLE 1—SUMMARY STATISTICS

	High APR card		Low APR card		Difference	
	Mean	SD	Mean	SD	Mean	SD
	(1)		(2)		(3)	
<i>Card characteristics</i>						
APR: Purchases (percent)	22.87	4.80	16.56	6.40	6.30	5.85
APR: Cash advances (percent)	26.08	4.12	23.72	5.28	2.36	6.31
Monthly credit limit (£)	6,388.77	4,443.05	6,013.20	4,092.41	375.57	4,856.48
<i>Spending (£)</i>						
Purchases	128.09	432.43	116.53	397.63	11.56	570.04
Purchases if > £0	380.17	672.79	360.06	629.70	-2.80	798.02
Cash advances	6.47	73.29	5.81	73.74	0.66	97.25
Cash advances if > £0	216.98	366.68	215.01	395.20	-5.42	352.15
<i>Payments (£)</i>						
Repayments	259.76	733.92	229.69	657.60	30.07	913.65
<i>Interest paid (£)</i>						
Purchases	38.48	59.49	28.97	48.32	9.51	61.64
Cash advances	1.49	10.73	0.91	7.13	0.58	11.88
<i>Card cycle (£)</i>						
Closing balance	3,020.54	3,115.48	3,032.15	2,967.13	-11.61	3,478.14
Revolving balance	2,200.01	2,890.49	2,053.68	2,796.17	146.33	3,082.07
Minimum amount due	63.24	68.84	56.80	58.32	6.43	71.55
<i>Card status</i>						
Predicted charge-off rate (percent)	1.80	3.03	1.65	2.56	0.13	3.11
Tenure (months since account opened)	104.82	78.13	78.53	70.10	26.30	84.55
Number of account-months	394,111		394,111		394,111	

Notes: Summary statistics for the two-card sample restricted to individual \times months in which individuals face an economically meaningful allocative decision. See Section IB for more details on the sample construction. APR stands for annual percentage rate. Predicted charge-off rate is the predicted probability that the credit card is charged off within the next six months. The exchange rate was £1 = \$1.32 at the midpoint of our sample period.

on all cards fixed, it is optimal for individuals to make the minimum required payment on all of their cards, repay as much as possible on the card with the highest interest rate, and only allocate further payments to the lower interest rate cards if they are able to pay off the highest interest rate card in full.¹⁹

We focus on repayments, rather than other measures of credit card use like spending or revolving balances, because, for repayments, we can clearly define optimal behavior. In contrast, optimal spending may depend upon rewards programs, which we do not observe in our data.²⁰ We also do not focus on the optimality of revolving balance allocations because revolving balances are a “stock” that cannot typically be quickly adjusted.²¹ Thus, to determine whether revolving balances are “optimal,” we would need to take a stand on how individuals could reallocate revolving balances

¹⁹We explicitly rule out the possibility that choosing not to make the minimum payment on a lower interest rate card could be optimal. Failing to repay the minimum repayment would result in a penalty fee and a marker on the individual’s credit file.

²⁰While issuers typically incur only a small cost for the rewards they provide (approximately 1 percent: see Agarwal et al. 2015), individuals might value rewards (such as airline points) at a high enough value to affect optimal spending decisions.

²¹In particular, with the exception of balance transfer products in the prime credit card market, individuals can only reallocate their stock of revolving balances by adjusting the flow of spending and repayments on a month-by-month basis.

FIGURE 1. ACTUAL AND OPTIMAL PAYMENTS

Notes: Panel A shows the distribution of actual and optimal payments on the high interest rate card in the two-card sample. Panels B to D show radar plots of mean actual and optimal payments in the samples with three to five cards. In the radar plots, cards are ordered clockwise from the highest to the lowest APR (starting at the first node clockwise from noon). All samples are restricted to individual \times months in which individuals face an economically meaningful allocative decision. Sample sizes in panel A: 394,111; panel B: 264,420; panel C: 83,880; panel D: 19,120. See Section IB for details on the sample construction.

through counterfactual spending and repayment decisions over time, which would require us to know the individuals’ time preference and their expectations over future spending and repayment decisions.

Panel A of Figure 1 plots the distribution of actual and optimal payments in the baseline two-card sample. The distribution of actual repayments appears close to symmetric, with a mass point at 50 percent, and smaller mass points at 33 percent and 67 percent. In contrast, the distribution of optimal repayments is heavily weighted toward the high APR card. It is not optimal for individuals to place 100 percent of their payments on the high interest rate card because (i) they need to pay the minimum on the low interest rate card and (ii) they are sometimes able to pay off more than the full balance on the high interest rate card.

Summary data for actual and optimal repayments for the two-card sample are shown in Table 2. On average, individuals should allocate 70.7 percent of repayments

TABLE 2—ACTUAL AND OPTIMAL PAYMENTS, INTEREST SAVINGS FROM OPTIMIZING

	Mean	SD	Percentiles				
			10th	25th	50th	75th	90th
<i>Panel A. Actual and optimal payments on the high APR card</i>							
1. As percent total monthly payment							
Actual payment	51.22	24.21	16.86	33.33	50.00	67.99	84.78
Optimal payment	70.74	22.17	38.10	55.92	75.23	89.48	95.83
Difference	19.52	23.75	0.00	0.72	9.91	32.40	54.55
2. Payment in £							
Actual payment	259.76	733.92	25.00	45.49	100.00	200.00	450.00
Optimal payment	377.30	849.70	32.62	65.00	138.51	307.09	807.21
Difference	117.54	422.14	0.00	1.00	17.80	75.00	237.47
<i>Panel B. Annualized interest savings from optimizing credit card repayments</i>							
	Mean	SD	Percentiles				
			75th	90th			
Two cards	64.82	115.33	70.39	167.41			
Three cards	121.26	463.63	133.44	414.36			
Four cards	198.40	665.57	262.80	703.68			
Five cards	247.65	851.83	366.96	926.88			

Notes: Panel A shows summary statistics for actual and optimal payments on the high APR card. The top panel shows values as a percentage of total payments on both cards in that month. The bottom panel shows values in £. $N = 394,111$. Percentiles and other summary statistics are taken with respect to individual \times month observations. Panel B shows summary statistics for annualized interest savings from a counterfactual “steady state” where individuals optimize balances across the credit cards we observe in our data, subject to the constraint of not exceeding their credit limits. The two-card sample has $N = 394,111$, the three-card sample has $N = 264,420$, the four card sample has $N = 83,880$, and the five-card sample has $N = 19,120$. In both panels, the sample is restricted to individual \times months in which individuals face an economically meaningful allocative decision. See Section IB for more details on the sample construction. The exchange rate was £1 = \$1.32 at the midpoint of our sample period.

to the high APR card. If individuals were completely unresponsive to interest rates, we might expect them to place 50 percent of payments on the high interest rate card. On average, individuals allocate 51.2 percent to the high interest rate card, which is very close to the completely non-responsive baseline. Individuals, thus, misallocate 19.5 percent of their total monthly payment on average.

In online Appendix Figure A1, we plot misallocated repayments in *excess* of the minimum payment. That is, we subtract out the amount required to make the minimum payment on each card and then calculate the share of the remaining amount that is allocated across cards. On average, individuals should allocate 97.1 percent of payments in excess of the minimum to the high APR card, whereas in practice they actually allocate 51.5 percent to that card.²² Alternatively put, over 90 percent of individuals should put 100 percent of their excess payments on the high interest rate card but fewer than 10 percent do so. Summary data for payments in excess of minimum are shown in online Appendix Table A2.

Panels B to D of Figure 1 show radar plots of the average percentage of actual and optimal payments on each card for the samples with 3, 4, and 5 cards. In each of the plots, the cards are ordered clockwise from the highest to the lowest APR (starting at the first node clockwise from noon). The polygons for actual payments

²²The number is not exactly 100 percent because sometimes individuals can pay off the full balance by allocating a smaller amount, in which case they should allocate the remaining amount to the low interest rate card.

are symmetric, indicating that the actual percentage of payments is very similar across cards. The polygons for optimal payments show that it would be optimal to allocate a substantially higher percentage of payments to the highest APR card and a substantially lower percentage to the card with the lowest APR.

As we mention in the introduction, these findings on misallocation are strikingly similar to those documented by Ponce, Seira, and Zamarripa (2017) using a sample of Mexican credit card holders. In particular, the most comparable result is that the share of payments in excess of the minimum misallocated to the high APR card is 50 percent among Mexican credit card holders and 46 percent among UK credit card holders. This remarkable similarity shows that misallocation among Mexican credit card holders is not due to their relatively limited experience with credit cards; in the UK, market penetration is 66 percent and cards have been available since 1966.

A. Costs of Misallocation

What are the costs of the failure to optimize? Our baseline approach is to consider the annualized interest savings from a counterfactual “steady state” where individuals optimize balances across the credit cards we observe in our data, subject to the constraint of not exceeding their credit limits. For the two-card sample, we construct the optimal allocation by transferring balances from the high to the low interest rate card up to the point where the individual “maxes out” their low interest rate card. With multiple cards, we construct the optimal allocation by allocating as much of the aggregate balance as possible to the credit card with the lowest interest rate, then allocating any remaining balance to the card with the next lowest rate, and so on. The interest savings from this exercise can be thought of as the interest savings that could be achieved if the individual was immediately and costlessly able to conduct the optimal “balance transfer” of balances across cards.

Panel B of Table 2 presents the annualized interest savings from this exercise. Average interest savings are increasing across the number of cards, rising from £65 in the two-card sample to £248 in the five-card sample. Because the degree of misallocation is not declining in the economic stakes of the decision, individuals with larger balances and larger differences in interest rates have a substantial cost of misallocation, with the ninetieth percentile rising from £167 in the two-card sample to £927 in the five-card sample.

In online Appendix B, we present two additional sets of results on the cost of misallocation, focusing on the two-card sample to keep the analysis trackable. First, we repeat the interest savings calculations above for cards that were excluded by our sample restrictions. For some excluded observations, such as those with no revolving balances, the interest savings are zero. For others, such as observations where individuals pay the minimum on both cards, the counterfactual steady state yields interest savings. Total savings, which combine positive savings for borrowers and zero savings for non-borrowers, are roughly one-third those in the baseline sample.

Second, we consider an alternative approach to calculating the cost of misallocation where counterfactual interest costs are determined by simulating forward outcomes when individuals optimally repay their credit cards over time. This simulation is supposed to measure the gains from “learning” the optimal repayment rule, which the individual can then implement over time and incrementally shift their

balances across cards. While interest savings are small at first, we show that over a 12-month time horizon, the interest savings from this incremental approach is quite similar to the interest savings from our baseline steady-state counterfactual.

There are a number of caveats to these calculations. Since our sample covers approximately 40 percent of the market, we likely only observe a subset of an individuals' credit card portfolio. Allowing individuals to optimize over more cards would necessarily lead to a larger cost of misallocation. And of course, allowing individuals to optimize across different types of debt or across savings and borrowing products would lead to even larger values.

III. Optimization Frictions

In this section, we examine whether optimization frictions can explain repayment behavior. We start by examining the evidence for optimal inattention models and then turn to the evidence for models of learning.

A. Optimal Inattention

In optimal inattention models, individuals face a fixed cost of optimization and only "optimize" if the benefits from doing so are greater than this fixed cost (Sims 2003). Specifically, in our context, individuals are already making positive credit card repayments on all of their cards and therefore already paying the fixed cost of logging into their bank's website or sending a check. So by a fixed cost of optimization, we have in mind the time, psychological, or cognitive costs associated with making the optimal repayment relative to making a non-optimal payment amount.²³ For some individuals, the reduction in interest payments from cost-minimizing may be too low to rationalize incurring this fixed cost.

To investigate this potential explanation, we examine the correlation between the percentage of misallocated repayments and the economic stakes of the repayment decision in the two-card sample. We define misallocated payments as the difference between optimal and actual payments on the high APR card. We examine three measures of the economic stakes: (i) the difference in APR across cards, (ii) the total repayment made that month, and (iii) the "financial stakes" of the repayment decision, which is defined as the product of the difference in APR across cards and the total repayment made that month, and thereby captures the annualized financial stakes from the repayment decision. Since the gains from optimizing are increasing in each of these measures, under the fixed cost explanation, the percentage of misallocated repayments should be declining in these three measures. Moreover, for individuals with large economics stakes, we would expect the degree of misallocation to be close to zero.²⁴

²³This contrasts with optimal mortgage refinancing (e.g., Keys, Pope, and Pope 2016), a setting where optimization would require actively soliciting a new mortgage offer.

²⁴These measures of economics stakes are not randomly assigned. However, it is important to note that the lack of random assignment is only a threat to "external validity" and not to "identification." Specifically, the fact that there are some individuals who do not optimize despite large incentives to do so implies that there are some individuals whose behavior cannot be rationalized by an inattention model. What requires a stronger assumption is to infer from this pattern that even individuals with small gains from optimization would still not optimize if they faced large incentives to do so.

FIGURE 2. MISALLOCATED PAYMENTS BY ECONOMIC STAKES

Notes: Figure shows binned scatter plots (with 20 equally sized bins) of misallocated payments against the difference in APR across cards (panel A), the total value of payments within the month in pounds (panel B), and the difference in APR multiplied by the total value of payments within the month (panel C). Local polynomial lines of best fit, based on the non-binned data, are also shown. The two-card sample is restricted to individual \times months in which individuals face an economically meaningful allocative decision. See Section IB for details on the sample construction.

Panel A of Figure 2 shows a binned scatter plot of the percentage of misallocated payments against the difference in APR between the high and low interest rate cards.²⁵ The flat relationship indicates that individuals are not less likely to misallocate repayments even when there is a large APR difference (more than 15 percentage points). Panel B of Figure 2 shows a binned scatter plot of the percentage of misallocated payments against total repayments on both cards. Again, there is no evidence of a decreasing relationship. Indeed, the relationship is increasing because individuals who make the largest payments can cover the minimum on the low APR card with a smaller percentage of their overall allocation and thus *should* allocate an even larger fraction of payments to the high APR card. Panel C shows there is no evidence of a decreasing relationship between the percentage of misallocated payments and the financial stakes. The relationship is slightly increasing for the same reason as the relationship with total payments. Table 3 presents summary statistics

²⁵The binned scatter plot is constructed by partitioning the x -axis variable into 20 equal-sized groups and plotting the mean of the y -axis and x -axis variables for each group. See Chetty, Friedman, and Rockoff (2014) for more details on the binned scatter plot methodology.

TABLE 3—ACTUAL AND OPTIMAL PAYMENTS ON HIGH APR CARD BY QUINTILES OF ECONOMIC STAKES AND CARD AGE

	Quintiles of panels A–E				
	(1)	(2)	(3)	(4)	(5)
<i>Panel A. Difference in APR</i>					
Difference in APR (percent)	0.81	2.03	3.78	6.44	14.98
Actual payment (percent)	49.79	50.27	50.98	51.86	53.19
Optimal payment (percent)	71.12	70.78	70.34	70.17	71.26
Difference (percent)	21.33	20.51	19.36	18.32	18.07

Difference (percent)	29.36	29.29	28.84	28.31	27.48

Notes: Summary statistics for actual and optimal payments on the high APR card by quintiles of economic stakes and card age. Cells report mean values within the quintile. The sample is restricted to individual \times months in which individuals face an economically meaningful allocative decision. $N = 394,111$. See Section IB for more details on the sample construction. The exchange rate was £1 = \$1.32 at the midpoint of our sample period.

on actual, optimal, and misallocated payments by quintiles of these measures of economics stakes.²⁶

B. Learning

An alternative explanation for the observed non-optimal behavior is that individuals learn over time (e.g., since opening a card) and that our analysis of the cross-sectional distribution of repayments masks this learning behavior. A model with time-varying adjustment costs (in the spirit of Calvo 1983) would also generate a gradual reduction in the degree of misallocation over time.

Panel A of Figure 3 examines this explanation by showing a binned scatter plot of the percentage of misallocated payments against the age (in months) of the high APR card. For this analysis, we restrict the sample to individuals who open a high

²⁶Online Appendix Figure A2 and Table A4 present the analogous results for misallocated payments in excess of the minimum payment.

FIGURE 3. MISALLOCATED PAYMENTS BY CARD AGE AND DIFFERENCE IN DUE DATES

Notes: Figure shows binned scatter plots (with 20 equally sized bins) of misallocated payments against the difference in payment due dates (panel A) and age of the high APR card (panel B). Local polynomial lines of best fit, based on the non-binned data, are also shown. The two-card sample is restricted to individual \times months in which individuals face an economically meaningful allocative decision. See Section IB for details on the sample construction.

APR during our sample period and for whom we can observe economically meaningful allocation decisions for ten consecutive months. In the plot, the horizontal axis starts in the second month after opening, since this is the first month in which individuals could have a balance on the high APR card to repay. The plot shows no evidence of a reduction in the percentage of misallocated repayments over time.²⁷ This finding suggests that neither learning nor time-varying adjustment costs can explain the observed non-optimizing behavior.

A related explanation is that individuals have difficulty optimizing repayments across cards when the due dates are far apart in time. From a cognitive perspective, individuals may be less likely to process credit card repayments as a joint decision when the due dates are far apart. From a budgetary perspective, individuals may face within-month liquidity constraints that prevent them from optimally reallocating payments. For example, individuals might receive their paycheck between credit card due dates, and therefore have different amounts of cash-on-hand when making their payments. Panel B of Figure 3 examines this explanation by showing a binned scatter plot of the percentage of misallocated payments against the difference in payment due dates.²⁸ The flat relationship indicates that these type of within-month allocation frictions cannot explain our result.

While it would be tempting to go beyond this simple analysis and try to quantify the fixed costs required to rationalize observed repayment behavior, doing so would require making strong, untestable assumptions. In particular, a key decision is whether to model optimization frictions as a fixed cost that needs to be paid every

²⁷Table 3 shows the summary statistics that correspond to this figure. Online Appendix Figures A3 and A4 present the analogous results for misallocated payments in excess of the minimum payment.

²⁸Table 3 shows the summary statistics that correspond to this figure. Online Appendix Figures A3 and A4 present the analogous results for misallocated payments in excess of the minimum payment.

period (e.g., a transaction cost of adjusting repayments) or as a fixed cost that only needs to be paid once (e.g., a one-time cognitive cost of learning the optimal repayment rule). The estimated fixed costs would largely be determined by this modeling decision. If we assumed there was a period-by-period fixed cost, repayment behavior could be rationalized by modest optimization frictions. If, instead, we assumed there was a one-time fixed cost, the benefits of learning the optimal rule could be as large as the discounted sum of interest savings from optimal credit card payments over the life cycle, which would imply a very large fixed cost of adjustment. Since that data do not provide us with guidance on the appropriate modeling assumption, we are hesitant to undertake this exercise.

IV. Heuristics

If individuals do not allocate their payments in an optimal, or constrained optimal, manner, what explains credit card repayments? In the remainder of this paper, we evaluate heuristics that might better explain the allocation of repayments. In this section, we introduce the set of heuristics that we consider. In Section V, we evaluate the explanatory power of these heuristics.

A. Balance Matching

We first consider a balance-matching heuristic under which individuals match the share of repayments on each card to the share of balances on each card. Let $k = 1, \dots, K$ index cards, p_k indicate payments, and q_k indicate balances. Balance-matching payments are given by

$$(1) \quad \frac{p_k}{\sum_{\kappa=1}^K p_{\kappa}} = \frac{q_k}{\sum_{\kappa=1}^K q_{\kappa}} \quad \text{for } k = 1, \dots, K,$$

subject to the constraint that the individual pays at least the minimum and no more than the full balance on any of their cards.²⁹

Repayments consistent with balance matching could arise from the salient placement of balances on credit card statements and the broad tendency for human (and other species) to engage in “matching behavior” in related choice environments. As shown in online Appendix Figure A5, balances are perhaps the most prominently displayed element on credit card statements. The psychological theory of anchoring (Tversky and Kahneman 1974) suggests that individuals might make payments in relation to saliently displayed balances (instead of less saliently displayed interest rates).^{30,31}

²⁹In the two-card sample, only 13.0 percent of observations are affected by these constraints. In nearly all of these cases, the balance-matching payment is less than 2 percentage points below the minimum payment amount. Treating these observations in other ways (e.g., dropping these observations) does not have a material impact on the results.

³⁰A second reason why balances may be more salient is that balances are denoted in the same units as repayments (£), whereas APR take on different units (percent).

³¹Balances also enter the minimum payment formula. Therefore, at least in principle, repayments might depend on balances indirectly through the minimum payment amount. We discuss this issue in online Appendix C and show that this channel does not explain our results.

The literature on matching behavior traces back to Herrnstein (1961), who showed that pigeons peck keys for food in proportion to the time it takes the keys to rearm rather than concentrating their effort on the key that rearms most quickly. Follow-up studies replicated Herrnstein's "matching law" among pigeons (Baum 1974, Miller 1976) and documented similar behavior among rats (Jacquet 1972), fish (Behrend and Bitterman 1961), and humans when undertaking more complex tasks (e.g., Skinner et al. 1996). Writing at the time, Arrow (1958) noted that these results challenged conventional economic models of behavior.³²

Matching behavior has perhaps been most widely documented among humans in repeated lottery choice experiments. In a typical study, subjects are asked to make repeated choices between, say, a gamble with a 70 percent probability of winning and one with a 30 percent probability of winning. In behavior known as "probability matching," subjects consistently place bets in proportion to the probabilities of winning, even though betting on the option with the highest probability first-order stochastically dominates any other decision. The most well-known papers in the literature are Rubinstein (2002), Gal (1996), and Loomes (1998). See Vulkan (2000) for a review paper that documents probability matching, and its limitations, across 22 repeated lottery experiments.

Of course, we do not propose balance matching as a precise description of individual repayment behavior. Pigeons do not measure the time it takes the keys to rearm with a stopwatch and we do not mean to suggest that individuals use long division to calculate the share of repayments that should be allocated to each card. Instead, we propose that individuals use balance matching as an "anchor" for their repayment behavior (Tversky and Kahneman 1974). Indeed, since credit card balances are fairly stable over time, an individual could approximate a balance-matching rule without knowing the exact balance on each card that month.³³

Finally, as we mention in the introduction, repayments consistent with balance matching could arise from individuals repaying a constant percentage of the balance on each card in a given month. If this percentage changes within individuals over time (e.g., 10 percent in January, 15 percent in February, etc.), it would be difficult to distinguish a constant percentage model from a balance matching model. If this percentage is fixed within individuals over time, we could distinguish between these models using random time-series variation in balances. Unfortunately, we do not have random time-series variation in balances, and the observed variation is likely to be driven by factors that also affect repayment decisions.

B. $1/N$ Rule

The spike in repayments at 50 percent (see panel A of Figure 1) suggests that some individuals use a simple $1/N$ heuristic by which they make equal-sized repayments

³²"We have here an experimental situation which is essentially of an economic nature in the sense of seeking to achieve a maximum of expected reward, and yet the individual does not in fact, at any point, even in a limit, reach the optimal behavior. I suggest that this result points out strongly the importance of learning theory, not only in the greater understanding of the dynamics of economic behavior, but even in suggesting that equilibria maybe be different from those that we have predicted in our usual theory." Arrow (1958, p. 14).

³³Ponce, Seira, and Zamarripa (2017) show that there is a positive correlation between the share of payments allocated toward cards and the share of debt held on cards, suggesting an approximate balance-matching rule may be at work among their sample of Mexican cardholders.

across cards, analogous to the $1/N$ heuristic documented in defined-contribution savings decisions (Benartzi and Thaler 2001). In particular, the excess mass of individuals who make payments at a one-to-one ratio is approximately 8.2 percent. If we add in the excess mass at one-to-two and two-to-one ratios, we can explain 11.7 percent of repayments.³⁴

While it might be nice to conclude that 11.7 percent of individuals repay according to a $1/N$ rule, there are a number of factors which suggest a more nuanced interpretation of the data. First, the $1/N$ rule could be interpreted as an anchor that individuals do not implement exactly. For example, an individual who pays £250 on card A and £225 on card B might be intending to split repayments. To account for this possibility, we will measure the performance of the $1/N$ heuristic in our goodness-of-fit analysis below. This analysis will gauge how well the $1/N$ heuristic fits the data, even when it does not fit behavior exactly.

A second nuance arises from the fact that $1/N$ behavior is disproportionately concentrated among individuals who “round” their payments to £50, £100, £200, and so on. If an individual rounds up a payment on card A from £80 to £100 and rounds down a payment on card B from £120 to £100, then the individual would appear as if they intended to make equal-sized payments, even though, absent rounding, the share of payments on each card would be substantially different from 50 percent.

Figure 4 investigates this competing explanation for the spike at 50 percent. Panel A plots the distribution of payments on the high APR card in pounds, and shows substantial evidence of rounding. We calculate that 19.2 percent of payments take on values that are multiples of £100, and 33 percent of payments take on values that are multiples of £50 (which obviously includes payments that are multiples of £100). Panels B and C show the percentage of payments on the high APR card, splitting the sample by whether the individual makes round number payments (defined as multiples of £50) or “non-round” number payments on the high APR card.³⁵

The plots show that the peaks at 50 percent (as well as 33 percent and 66 percent) are heavily concentrated among individuals who make round number repayments. In the non-round sample, there is only a small spike at 50 percent, and no discernible spike at 33 percent or 66 percent. Thus, at the extreme, we cannot reject the view that nearly all of the spike at 50 percent is due to rounding. However, since we do not have random variation in whether individuals round, we cannot rule out the other extreme that all of these individuals would have allocated 50 percent on the high APR card if they had counterfactually not rounded their payments.

Thus, the quantitative importance of $1/N$ depends upon what assumptions we are willing to make. If we think $1/N$ is something that individuals implement exactly, then the $1/N$ rule captures at most 11.7 percent of repayments, and possibly a lower percentage if we believe that some of this is due to rounding. If we view $1/N$ as an

³⁴By excess mass, we are using the terminology that Saez (2010) and Chetty et al. (2011) use to describe bunching in response to kinked tax schedules. In our context, the excess mass is the area in excess of what is predicted by a linear extrapolation between points on the histogram just to the left and the right of the $1/N$ values.

³⁵The propensity to make round number payments is highly correlated across cards within an individual \times month. We calculate that 73 percent of individuals who make a round number payment on the high APR card also make a round number payment on the low APR card, and 78 percent of individuals who make a non-round number payment on the high APR card also make a non-round number payment on the low APR card. Dividing the sample into individuals who make round number repayments on both cards, non-round number repayments on both cards, and a mix of round and non-round repayments complicates the exposition without changing the results.

Panel A. Density of payments (£s)

Panel B. Density of payments (percent), round number values

Panel C. Density of payments (percent), non-round number values

FIGURE 4. ROUNDING AND THE $1/N$ RULE

Notes: Panel A shows the distribution of payments on the high APR card in £s (excluding the top decile of payments). Panel B plots the distribution of payments on the high APR card in percent, among individuals who make round number payments (exact multiples of £50). Panel C plots the distribution of payments on the high APR card in percent, among individuals who make non-round number payments (not multiples of £50). The round and non-round samples are defined by repayments on the high APR card. See footnote 35 for details. The two-card sample is restricted to individual \times months in which individuals face an economically meaningful allocative decision. See Section IB for details on the sample construction.

anchor that individuals approximate, then it is best to judge the empirical relevance of this measure in the goodness-of-fit analysis that follows.³⁶

C. Other Heuristic Models of Repayment

We also consider four alternative heuristics that capture intuitive economic and non-economic approaches to the allocation of payments. Some of these heuristics are based on the *capacity* of a credit card, which we define as the difference between the credit limit and current balance in pounds. We describe these heuristics for the two-card sample, but they could be naturally extended to settings with three or more cards.

³⁶ In the goodness-of-fit analysis of the $1/N$ heuristic, we drop observations where predicted values are less than the minimum payment or more than the full payment on at least one card.

- **Heuristic 1:** *Repay the card with the lowest capacity.*—Allocate payments to the lowest capacity card, subject to paying the minimum on both cards. Once capacity is equalized across cards, allocate additional payments to both cards equally. Intuitively, by focusing payments on the card with the lowest capacity, this heuristic reduces the risk that an accidental purchase will put an individual over their credit limit, which would incur an over-limit fee and marker on the individual’s credit file.
- **Heuristic 2:** *Repay the card with the highest capacity.*—Allocate payments to the highest capacity card, subject to paying the minimum on both cards. Once the highest capacity card is fully repaid, allocate remaining payments to the other card. Intuitively, by allocating payments to the card with the highest capacity, this heuristic creates maximum “space” for making a large purchase on a single card (e.g., buying a television).
- **Heuristic 3:** *Repay the card with the highest balance.*—Allocate payments to the highest balance card, subject to paying the minimum on the other card. Once balances are equalized across cards, allocate additional payments to both cards equally. If individuals dislike having a credit card with a large balance, this heuristic reduces the maximum balance they are carrying, and thus might explain repayment behavior.
- **Heuristic 4:** *Repay the card with the lowest balance (debt snowball method).*—Allocate payments to the lowest balance card, subject to paying the minimum on the other card. Once the balance on the lowest balance card is paid down to zero, allocate any additional payments to the other card. This heuristic is sometimes referred to as the debt snowball method by financial advisors. Proponents argue that paying off a card with a low balance generates a “win” that motivates further repayment behavior.³⁷ If an individual fully pays off a card, this heuristic has the additional benefit of “simplifying” the individual’s debt portfolio. See Amar et al. (2011) and Brown and Lahey (2015) for laboratory evidence on this approach to debt repayment.

D. Interest Payments under Different Heuristics

How costly would it be for consumers to follow these heuristics? We calculate annualized interest savings for the steady-state balances that would arise from each of the different heuristic models. For example, if consumers follow a balance matching heuristic, then the process of making larger payments on the card with the larger balance would cause balances to asymptote to a steady state with equal balances on each card.³⁸

³⁷For example, syndicated radio host Dave Ramsey argues: “But when you ditch the small debt first, you see progress. That one debt is out of your life forever. Soon the second debt will follow, and then the next. These little wins will give you a confidence boost, you’ll see that the plan is working, and you’ll stick to it” (see <https://www.daveramsey.com/blog/top-5-debt-snowball-questions-answered>).

³⁸The steady-state outcomes of the other heuristics are as follows. Under the $1/N$ heuristic, payments are equal across cards, and the steady-state balances are unchanged relative to the status quo. Under Heuristic 1 (repay the card with the lowest capacity), payments are prioritized to the card with the lowest capacity, and in steady-state capacities on the 2 cards are equalized, subject to credit limits. Under Heuristic 2 (repay the card with the highest capacity), payments are prioritized to the card with the highest capacity, and in steady-state balances are reduced as much as possible on that card, subject to credit limits. Under Heuristic 3 (repay the card with the highest balance),

Online Appendix Table A5 shows the distribution of annualized interest savings (compared to actual interest payments) under each heuristic for the two-card sample. We show the interest savings from optimal payments on the first row as a benchmark and omit the $1/N$ heuristic because steady-state balances are unchanged and interest savings are therefore zero. All the heuristics have median savings close to zero, but have wide dispersion in savings or losses across observations. This wide dispersion occurs because the heuristics prioritize payments to cards based on balances (and credit limits), which are not systematically correlated with the optimal behavior of prioritizing payments toward the high APR card.

V. Testing Repayment Models

We evaluate balance matching and the other heuristics using two statistical approaches. First, we measure the distance between observed and predicted behavior using standard measures of goodness-of-fit (root mean square error, mean absolute error, Pearson's ρ). The goal of this analysis is to find the single model that best fits the data. Second, we evaluate the performance of our models in "horse race" type analysis where we determine the best fit model on an observation-by-observation basis. We conduct binary comparisons where we compare each model to a single alternative, and horse races with three or more models, which allows us to classify observations into heterogeneous types. We also examine the persistence of the best fit model within individuals over time.

A. Goodness-of-Fit

We start by presenting visual evidence on the goodness-of-fit of the balance-matching heuristic. Figure 5 examines the fit in the two-card sample. The left column shows the marginal distributions of actual and balance-matching payments on the high APR card. The right column displays the joint distribution using a contour plot. The top row shows these relationships for the baseline sample and the bottom row focuses on the sample with non-round number payment amounts. The sample with round number payment amounts is shown in online Appendix Figure A6.

The histograms (left column) show that the marginal distributions of actual and balance-matching payments are quite similar, except for the spikes at 33 percent, 50 percent, and 66 percent. The higher mass along the 45-degree line in the joint densities (right column) indicates that actual and balance-matching payments are strongly correlated. The correlation is stronger in the non-round payment sample (and weaker in the round number payment sample).³⁹

payments are prioritized to the card with the highest balance, and in steady state the balances on the 2 cards are equalized, subject to credit limits. Under Heuristic 4 (repay the card with the lowest balance), payments are prioritized to the card with the lowest balance, and in steady-state balances are minimized on that card, subject to credit limits.

³⁹ The weaker correlation in the round payment sample is consistent with a two-stage model in which individuals first decide to make balance-matching payments and then add noise to the process by rounding their repayment amounts. While the heaping in panel A of Figure 4 provides clear evidence of rounding, estimating a two-stage model where individuals round in the second stage is difficult because the second stage rounding function is not "invertible." That is, it is hard to know whether an individual who is paying £100 would have counterfactually paid £95 or £105 if they had not rounded their payment.

Panel A. Baseline sample

Panel B. Non-round number payment sample

FIGURE 5. BALANCE MATCHING

Notes: Left panels show the distribution of actual and balance-matching payments on the high APR card. Right panels show the joint density of actual and balance-matching payments. Panel A shows the baseline sample, panel B restricts the sample to non-round payment amounts (not multiples of £50). Round and non-round samples are defined by repayments on the high APR card. See footnote 35 for details. The two-card sample is restricted to individual \times months in which individuals face an economically meaningful allocative decision. See Section IB for details on the sample construction.

Figure 6 examines the fit of the balance-matching model in the samples with 3, 4, and 5 cards. The left column shows marginal distributions of the share of payments on the highest APR card. The right column shows radar plots of the average share of actual and balance-matching payments. In each of the radar plots, the cards are ordered clockwise from the highest to the lowest balance (starting at the first node clockwise from noon). The distribution of payments on the high APR card (left column) is similar to predicted payments under balance matching. The radar plots (right column) show that the average share of payments is fairly close to those predicted by balance matching, especially compared to the radar plots that examine optimal repayment behavior (Figure 1).

We formally measure the performance of the balance matching and alternative models using three standard measures of goodness-of-fit: the square root of the mean square error (RMSE), the mean absolute error (MAE), and the correlation between

Panel A. Three cards

Panel B. Four cards

Panel C. Five cards

FIGURE 6. DISTRIBUTION OF ACTUAL AND BALANCE-MATCHING PAYMENTS ON MULTIPLE CARDS

Notes: Left column shows the marginal distributions of actual and balance-matching payments on the high APR card. Right column shows radar plots of the mean percentage of actual and balance-matching payments allocated to each card. In the radar plots, cards are ordered clockwise from the highest to the lowest balance (starting at the first node clockwise from noon). All samples are restricted to individual \times months in which individuals face an economically meaningful allocative decision. See Section IB for details on the sample construction.

actual and predicted payments (Pearson's ρ).⁴⁰ To help interpret the goodness-of-fit values, we also establish lower and upper benchmarks. For a lower benchmark, we calculate goodness-of-fit under the assumption that the percentage of repayments on the high APR card is randomly drawn from a uniform distribution with support on the 0 percent to 100 percent interval. To provide an upper benchmark, we use machine learning techniques to construct a set of purely statistical models of repayment behavior. Specifically, we estimate decision tree, random forest, and extreme gradient boosting models of the percentage of payments allocated to the high APR card. We use the same set of variables which enter into our heuristics (APRs, balances, spending, and credit limits on both cards) as input variables and "tune" the models to maximize out-of-sample power using standard methods from machine learning.⁴¹ We use 80 percent of the data sample as the "training" sample and measure out-of-sample fit on a 20 percent "hold-out" sample. For consistency, in the analysis that follows, we compare all models using the hold-out sample. Technical details are provided in online Appendix A.

Figure 7 shows these measures of goodness-of-fit under the different models. (Online Appendix Table A6 shows the underlying numerical amounts with bootstrapped standard errors, constructed by drawing with replacement from the hold-out sample.) The optimal model yields only a very small improvement in the RMSE and MAE relative to the lower benchmark. The optimal model does generate a meaningful increase in the Pearson correlation, although this is partly because the lower benchmark (uniformly distributed random amount) is constructed to have a Pearson correlation of zero. The other heuristics perform similarly poorly, with the goodness-of-fit measures generally falling less than one-quarter of the way between the lower and upper benchmarks.⁴²

The goodness-of-fit measures for the balance-matching model fall slightly more than halfway between the lower and upper benchmarks, indicating that balance matching captures more than half of the "predictable variation" in repayment behavior. Online Appendix Figure A7 shows goodness-of-fit separately for the round and non-round samples (defined as multiples of £50). The balance-matching model captures a larger fraction of the predictable variation in the non-round number sample, which is consistent with the two-stage model of payments discussed in footnote 38.

There are two ways to view the performance of the balance-matching model relative to the upper benchmark provided by the machine learning models. The glass-half-full view is that being able to capture more than half of the predictable variation in repayment behavior with a simple balance matching model is useful. Balance

⁴⁰Pearson's ρ is also the square root of the R^2 from a univariate regression of actual payments on predicted payments.

⁴¹We view these machine learning models as "prior-free" models of repayment behavior. If we additionally include our candidate models (optimal, balance matching, and the other heuristics) as input variables, we obtain only small improvements in model fit.

⁴²Online Appendix Figure A8 shows the marginal distributions of actual and predicted payments under each of the alternative heuristics. One common feature of these alternative heuristics is that they predict that individuals should often concentrate their excess payments on a single card. For instance, under Heuristic 1 (repay the card with the lowest capacity), individuals should fully allocate repayments, in excess of the minimum, to the card with the lowest capacity until the point where both cards have equal capacity remaining. Individuals, however, seem to avoid "corner solutions" in their repayment behavior. As a result, the alternative heuristics over-predicted the share of individuals who allocate a very small (less 10 percent) or very large (greater than 90 percent) share of payments to the high APR card.

FIGURE 7. GOODNESS-OF-FIT FOR DIFFERENT MODELS

Notes: Goodness-of-fit for different models of the percentage of payments on the high APR card. The left panel shows the root mean square error (RMSE), the middle panel shows the mean absolute error (MAE), and the right panel shows the Pearson Correlation Coefficient, which can also be interpreted as the square root of the R^2 . Random has repayments on the high APR card randomly drawn from a uniform distribution with support on the 0 percent to 100 percent interval. Optimal is pay minimum required payment on all of their cards, repay as much as possible on the card with the highest interest rate, and only allocate further payments to the lower interest rate cards if they are able to pay off the highest interest rate card in full. Heuristic 1 is repay the card with the lowest capacity. Heuristic 2 is repay the card with the highest capacity. Heuristic 3 is repay the card with the highest balance. Heuristic 4 is repay the card with the lowest balance (debt snowball method). Balance matching is match the share of repayments on each card to the share of balances on each card. Decision Tree, Random Forest, and Gradient Boost are machine learning models that predict the share of repayments on the high APR card using these methods. The two-card sample is restricted to individual \times months in which individuals face an economically meaningful allocative decision. Goodness-of-fit is calculated using the 20 percent hold-out sample. See Section IB for details on the sample construction.

matching is easy to understand, has a psychological underpinning based on existing theories of behavior (e.g., probability matching, Herrnstein's matching law), and might provide intuition for individual behavior in yet-to-be-studied environments. The glass-half-empty perspective is that machine learning techniques provide higher predictive power. Thus, if the goal is prediction, rather than understanding human behavior, machine learning techniques may be preferable.

B. Horse Races between Alternative Models

We next evaluate these models using "horse races" where we determine the best fit model on an observation-by-observation basis. A model that fits a smaller number of observations very poorly, but a larger number quite well, might perform poorly under the goodness-of-fit analysis, but would perform well under this approach.

Our ability to identify the best-fit model on an observation-by-observation basis is due to the unique nature of the credit card repayment decision. As discussed in the introduction, what sets credit card repayments apart from many other financial decisions is that optimal behavior does not depend on preferences (such as risk preferences or time preferences). If preferences were important for optimal behavior, then conducting this type of exercise would require recovering preferences at the individual level, which would constitute a significant empirical challenge.

Table 4 shows results of this horse race analysis in the pooled sample of individual \times months. Panel A compares each of our models one-by-one against the lower

Notes: Table shows percentage of individual × month observations that are best fit by different models of repayment behavior. The target variable is the share of repayments on the high APR card. Panel A compares each of our models one-by-one against the lower benchmark where the percentage of repayments on the high APR card is randomly drawn from a uniform distribution with support on the 0 percent to 100 percent interval. Panel B compares each of the models one-by-one to the balance-matching model. We exclude a comparison of balance matching and the uniform model, since it was shown in Panel A. Uniform has repayments on the high APR card randomly drawn from a uniform distribution with support on the 0 percent to 100 percent interval. Balance matching is match the share of repayments on each card to the share of balances on each card. Optimal is pay minimum required payment on all of their cards, repay as much as possible on the card with the highest interest rate, and only allocate further payments to the lower interest rate cards if they are able to pay off the highest interest rate card in full. Heuristic 1 is repay the card with the lowest capacity. Heuristic 2 is repay the card with highest capacity. Heuristic 3 is repay the card with the highest balance. Heuristic 4 is repay the card with the lowest balance (debt snowball method). Decision Tree, Random Forest, and XGB are machine learning models that predict the share of repayments on the high APR card using these methods. Samples are restricted to individual × months in which individuals face an economically meaningful allocative decision. All results shown in the table are based on the 20 percent hold-out sample. See Section IB for more details on the sample construction.

benchmark where the percentage of repayments on the high APR card is randomly drawn from a uniform distribution with support on the 0 percent to 100 percent interval. In a binary comparison, balance matching is the best fit model for 67.1 percent of observations, or about twice the percentage of the uniform benchmark. The optimal model and the other heuristics are the closest for slightly more than half of the observations, and therefore perform only slightly better than the uniform benchmark. The machine learning models have the best fit for between 69.0 percent and 76.5 percent of observations, which is similar to balance matching.⁴³

⁴³ Since the machine learning models were tuned to minimize RMSE, it is natural for these models to perform relatively better when evaluated using RMSE (and other distance metrics) than when evaluated using this type of horse race analysis.

Panel B of Table 4 compares each of the models one-by-one to the balance-matching model.⁴⁴ In a horse race with the optimal model, balance matching has the best fit for slightly more than two-thirds of observations. When compared with the other heuristic models, balance matching is also the best fit for approximately two-thirds of observations. Balance matching performs comparably to, or only a little worse than, the machine learning models, with balance matching exhibiting the best fit for 40.9 percent to 50.0 percent of observations.⁴⁵

The binary comparisons are useful for finding the single model that fits the largest percentage of observations. A complementary approach is to conduct horse races with three or more models, which allows us to classify observations into heterogeneous types. One challenge with this exercise is that, simply by chance, virtually any model will have the best fit for some observations. To be able to interpret the results as reflecting heterogeneity in types, we need to be disciplined in choosing which models to include and to also compare the percentage of observations fit by a given model to the uniform benchmark.

Online Appendix Table A8 shows the results of this exercise. In column 1, we compare the optimal, $1/N$, and balance-matching models. These are the models that seem plausible based on economic theory (optimal) or evidence ($1/N$ and balance matching). In column 2, we add the uniform benchmark to the set of models. In both specifications, balance matching has the best fit for one-half of the observations. Optimal and $1/N$ capture slightly more than one-fifth of observations when we do not include the uniform benchmark, but perform only marginally better than the uniform benchmark when it is included.

To the extent that we think of the competing models as actually representing different models of individual decision-making, we would naturally expect the best-fit model to be persistent within individuals over time. Table 5 shows the within-person transition matrix for the best-fit model. The sample is restricted to individual \times months where we observe repayment behavior for at least two months in a row. For this exercise, we consider all the candidate models, and we fix the uniformly distributed repayment to be constant within individuals over time.⁴⁶

The table shows that balance matching exhibits a high degree of persistence, both in absolute value and relative to the other models of repayment behavior. Among individuals whose repayments are best fit by the uniform model in a given month, 23.2 percent make repayments that are closest to the uniform model in the next month. This persistence likely reflects the fact that balances and repayments are sticky over time: if the uniform model happens to be accurate in a given month, and balances and payments are sticky, then the uniform model, which is fixed to be constant within an individual over time, will mechanically be accurate in the next month as well.

The balance-matching model exhibits three-fold greater persistence than the uniform model. Among individuals whose repayments are closest to balance matching

⁴⁴ We exclude a comparison of the balance-matching and the uniform model, since it was shown in panel A.

⁴⁵ In unreported analysis, we examined whether there was correlation between the best fit model and postal code characteristics (such as postal code income and education). We were unable to detect any economically or statistically significant correlations. However, we caution against drawing too strong conclusions about heterogeneity, because we do not know whether postal code characteristics are good proxies for the demographic characteristics of our sample of individuals.

⁴⁶ We drop observations where there is a tie for the best fit heuristic. The number of ties is increasing in the number of models considered. However, the persistence of balance matching is not sensitive to the number of models.

TABLE 5—TRANSITION MATRIX FOR BEST-FIT MODEL

	Current period (%)							
	Balance			H 1	H 2	H 3	H 4	1/N rule
	Uniform	Matching	Optimal					
Uniform	23.18	56.71	0.24	1.53	0.35	2.24	0.59	15.18
Balance matching	8.24	83.06	0.13	1.37	1.18	1.07	1.13	3.82

1/N rule	18.99	27.89	0.13	2.39	0.40	1.33	0.27	48.61

Notes: Table shows transition matrix for the best-fit payment model. The target variable is the share of repayments on the high APR card. In each period, we allow the set J to encompass all of the candidate models, and we fix the uniformly distributed repayment to be constant within an individual over time. Balance matching is match the share of repayments on each card to the share of balances on each card. Optimal is to pay minimum required payment on all of their cards, repay as much as possible on the card with the highest interest rate, and only allocate further payments to the lower interest rate cards if they are able to pay off the highest interest rate card in full. Heuristic 1 is repay the card with the lowest capacity. Heuristic 2 is repay the card with highest capacity. Heuristic 3 is repay the card with the highest balance. Heuristic 4 is repay the card with the lowest balance (debt snowball method). 1/N is exactly split repayments across cards. Samples are restricted to individual \times months in which individuals face an economically meaningful allocative decision. All results shown in the table are based on the 20 percent hold-out sample. See Section IB for more details on the sample construction.

in a particular month, 83 percent make payments that are closest to balance matching in the next month. The high degree of persistence suggests that balance matching is more than a good statistical model but is actually capturing a stable feature of individual decision-making. The only other model that exhibits strong persistence is the 1/N rule, which again likely reflects that fact that 1/N repayments (or the tendency to round payments) is a stable feature of individual behavior.

C. Sensitivity Analysis

In online Appendix C, we present two sets of sensitivity analysis. First, for some credit cards, minimum payments are set as a proportion of balances. For these cards, balance matching behavior could instead arise from individuals making payments that are proportional to minimum payments. We rule out this explanation by showing that the balancing matching result holds among cards where minimum payments are not proportional to balances. Second, we investigate the sensitivity of our results to whether the individual uses automatic payment (autopay). We show that autopay is rare in our baseline sample (11 percent). However, when individuals use autopay, their propensity to misallocate and to follow a balance-matching rule is similar to that in the non-autopay sample, suggesting that our results are robust across these somewhat different choice environments.

D. Balances and APRs in Machine Learning Models

In addition to providing us with an upper benchmark, the machine learning models allow us to assess the relative importance of balances and APRs in predicting

repayment behavior. Specifically we calculate the variable importance, which can be thought of as the proportional increase in R^2 from adding a given variable to the model. Online Appendix Table A9 shows that APRs and balances are not strongly correlated. In cases where the variables are collinear, the interpretation of variable importance may be spurious (Mullainathan and Spiess 2017).

Consistent with the balance matching results, the machine learning models confirm that balances are hugely important for predicting behavior. Online Appendix Table A10 shows that balances have the highest variable importance in all of the models, with importance factors substantially larger than any of the other explanatory variables. Consistent with the poor fit of the optimal repayment rule, we find that APRs have the lowest variable importance across models. Online Appendix Table A11 shows minima and maxima of variable importance from models estimated on 10 partitions of the training sample. Unlike some other machine learning applications (e.g., Mullainathan and Spiess 2017), the ranges are narrowly spread around the baseline estimates from online Appendix Table A10, indicating that our variable importance measures are not particularly sensitive to random variation in the training dataset.

Taken together, our goodness-of-fit analysis supports the view that balance matching is a powerful predictor of credit card repayments, capturing more than half of the predictable variation in repayment behavior and performing substantially better than alternative models. In the horse race analysis, balance matching performs at a similar level to the machine learning models, and is highly persistent over time, suggesting it is more than a good statistical model but is actually capturing a stable feature of individual decision-making.

VI. Discussion

The fact that individuals do not repay credit cards optimally, and instead repay in proportion to balances, has implications for the industrial organization of credit card markets and public policy. While it is beyond the scope of the paper to rigorously examine these implications, we provide some initial thoughts below.

To think through the implications for consumer and producer surplus, consider a two-stage model of the credit card market. In stage 1, individuals shop for and select credit cards. In stage 2, individuals spend on and repay their credit cards. The analysis in this paper implies that conditional on reaching stage 2, individuals do not optimally concentrate their borrowing on their cheapest card. From the perspective of the issuer, this implies that being the high cost card in a consumers' portfolio can generate large stage 2 profits. However, to understand the full effect of non-optimal repayments on producer and consumer surplus, we need to understand how these stage 2 profits affect behavior in stage 1.

One possibility is that firms dissipate their stage 2 profits via competition for an "install base" of consumers in stage 1. If stage 2 profits lead firms to set very low stage 1 prices (e.g., teaser rates) to acquire an install base, then it is theoretically possible for firms to dissipate all of their stage 2 rents, and for consumer surplus to be similar to what it would be in a counterfactual scenario where consumers repay their balances optimally (although the timing of borrowing will still be distorted from the teaser rate). A second possibility is that firms dissipate some, per-

haps most, of their stage 2 profits in acquisition behavior. The large number of mail solicitations, aggressive new card promotions, and heavy television advertising in the industry is consistent with this theory. To the extent that much of these acquisition costs are businesses stealing from rivals, and not category expansion, this expenditure can be thought of as a deadweight loss. A third possibility is that firms do not dissipate much of their stage 2 profits in stage 1. This could occur because there are decreasing returns to acquisition activity (conditional on sending a mail solicitation every week, the marginal return to an additional mailer might be quite small). Adjudicating between these different possibilities is important but beyond the scope of this paper.

From a policy perspective, a natural response to the observed non-optimality of repayments is to make interest rates more salient. While Seira, Elizondo, and Laguna-Müggenburg (2017) found no effect of interest rate salience on indebtedness and defaults in their study of Mexican credit card holders, there may be alternative ways of presenting interest rate information that successfully shift behavior. A broader policy response is to make it easier for consumers to share credit card data with third parties, such as FinTech firms.⁴⁷ In principle, these firms could use these data to help consumers optimize their repayments across their credit cards, although there is no guarantee that they will nudge consumers in an optimal direction.

VII. Conclusion

In this paper, we used linked data on multiple cards from five major credit card issuers to study how individuals repay their debt. First, we showed that the allocation of repayments is highly non-optimal, with individuals allocating only 51.5 percent of their payments in excess of the minimum to the high APR card, relative to optimal repayments of 97.1 percent. These findings are almost identical to Ponce, Seira, and Zamarripa (2017), and indicate that the behavior they documented did not merely reflect limited consumer experience with credit cards in the Mexican market.

Second, we showed repayment behavior was inconsistent with models of optimization frictions. Specifically, we showed that degree of misallocation was invariant to the financial stakes of the repayment decision, implying that models of optimal inattention with a fixed cost of adjustment could not explain our findings. We also showed that the degree of misallocation is invariant to the time since account opening, suggesting that a learning model cannot explain observed behavior.

The third part of the paper showed that repayment behavior is consistent with a balance-matching heuristic under which the share of repayments on each card is matched to the share of balances on each card. In particular, we showed that balance matching captures more than half of the predictable variation in repayments, performs substantially better than other models, and is highly persistent within individuals over time. Making repayments in proportion to balances could arise from broad tendency for humans, and other species, to engage in “matching behavior” in related choice environments, but could also arise from individuals

⁴⁷For instance, recently implemented Open Banking regulation in the United Kingdom requires large banks, at their consumers’ discretion, to give third parties access to account data through secure application programming interfaces (APIs).

repaying a constant percentage of their balances across cards. Unpacking the underlying explanations for repayment behavior is a fruitful area for future research.
